Cell formation by myxozoan species is not explained by dogma

David J. Morris*

Eukaryotes form new cells through the replication of nuclei followed by cytokinesis. A notable exception is reported from the class Myxosporea of the phylum Myxozoa. This assemblage of approximately 2310 species is regarded as either basal bilaterian or cnidian, depending on the phylogenetic analysis employed. For myxosporeans, cells have long been regarded as forming within other cells by a process referred to as endogenous budding. This would involve a nucleus forming endoplasmic reticulum around it, which transforms into a new plasma membrane, thus enclosing and separating it from the surrounding cell. This remarkable process, unique within the Metazoa, is accepted as occurring within stages found in vertebrate hosts, but has only been inferred from those stages observed within invertebrate hosts. Therefore, I conducted an ultrastructural study to examine how internal cells are formed by a myxosporean parasitizing an annelid. In this case, actinospore parasite stages clearly internalized existing cells; a process with analogies to the acquisition of endosymbiotic algae by cnidian species. A subsequent examination of the myxozoan literature did not support endogenous budding, indicating that this process, which has been a central tenet of myxozoan developmental biology for over a century, is dogma.

Keywords: Myxosporea; actinospore; development; Myxozoa; endogenous budding; Paramyxida

1. INTRODUCTION

The formation of cells is a fundamental process of biology. Within the Metazoa, new cells form by cytokinesis following either mitotic or meiotic division of the nucleus. Cytokinesis is initiated by the formation of a contractile ring that constricts the cytoplasm between the nuclei, finally cleaving the cell (Glotzer 2001). A notable exception to this process appears within the phylum Myxozoa—a species-rich group composed entirely of obligate parasites, some of which cause disease of substantial ecological and economic importance within the aquatic environment (Kent et al. 2001; Sitja-Bobadilla 2009). Here, cells have been reported as forming within other cells by a process referred to as endogenous budding (Lom & Dykova´ 2006).

Historically, their microscopic size, amoeboid nature and the formation of spores resulted in the Myxozoa being classified within the protistan class Sporozoa, which included other parasitic groups displaying endogenous cell formation (Bütschli 1881). However, the morphological similarity of polar capsules (organelles possessing an extruding filament observed in myxozoan spores) to cnidian nematocysts was repeatedly commented upon, with some authors promoting placement within the Metazoa (Grassé 1960; Lom 1969).

The majority of molecular phylogenies have confirmed that myxozoans are metazoans (Smothers et al. 1994). Several phylogenies have placed them with the Cnidaria, leading to suggestions that they be classified as cnidarians (Siddall et al. 1995; Jimenez-Guri et al. 2007). If this were adopted then the Myxozoa, with some 2310 described species, would represent a significant addition to cnidian diversity. However, the placement has proved controversial with other studies indicating that they are basal bilaterians (Schlegal et al. 1996; Zrzavý & Hypša 2003; Evans et al. 2008). This ambiguity has led to the suggestion that the Myxozoa may represent a distinct sub-kingdom within the Metazoa between the Cnidaria and Bilateria (Cavalier-Smith 1998).

Reports of endogenous budding arise from the myxozoan class Myxosporea that represent the majority of species; the sister class Malacosporea (three described species) obtain internal cells through engulfment (Morris & Adams 2007, 2008). Where known, myxosporeans have an indirect life cycle incorporating a fish and an annelid host. Within the fish, the parasites may develop into multinucleated plasmodial stages. To form a cell, a nucleus is considered to develop a surrounding mass of endoplasmic reticulum (ER), enclosing it together with some cytoplasm. The ER then transforms into a plasma membrane, resulting in a cell that is internal to the surrounding cell (Lom & Dyková 1992a). The multinucleated plasmodial cell is termed a ‘primary cell’ and the cells contained within this ‘secondary cells’. Where cells are contained within secondary cells, these are termed ‘tertiary cells’; representing a cell, within a cell, within a cell. With the possible exception of the protistan order Paramyxida, this remarkable and somewhat bizarre process (i.e. cell formation not involving an existing plasma membrane) is unique within Eukaryota (Lom et al. 1983).

In addition to fish, endogenous budding may occur during the intra-annelid development of myxosporeans (outlined in figure 1). The mature spores released from these hosts (termed actinospores) are multicellular, composed of a sporoplasm, three valve cells and three capulocogenic cells. The sporoplasm is the infective stage to the fish; the capsulogenic cells contain the polar capsules that anchor the spore to a potential host, while the

valve cells protect the sporoplasm and aid buoyancy (Lom et al. 1997). The sporoplasm is a multinucleated cell that possesses ‘germ’ cells within it, and endogenous budding is proposed to explain the origin of these cells (Lom & Dyková 1992; El-Matbouli & Hoffmann 1998). However, detailed ultrastructural studies regarding germ cell formation are lacking.

2. MATERIAL AND METHODS
The material used for this study was obtained from archival material from 2007 and consisted of two Tubifex tubifex oligochaetes collected from the same site and infected with the same species of aurantiactinomyxon-type myxosporean. The oligochaetes were collected, fixed and processed into Spurr’s resin for electron microscopy as detailed by Morris & Freeman (2010), additional ultrathin sections were cut and stained using uranyl acetate and lead citrate and examined at 120 kV using a Tecnai Spirit G2 electron microscope. A previous study had established that the aurantiactinomyxon had identical developmental characteristics between both oligochaete samples and has thus been considered to represent a single species with no evidence of a coinfection (Morris & Freeman 2010).

Twenty-four grids were examined, each holding a minimum of two ultrathin sections. Myxosporean stages observed were compared with previous reports from the literature to help construct the developmental pathway.

3. RESULTS
Both oligochaetes were heavily infected with the myxosporean, possessing numerous parasites, including binucleate proliferating stages and pansporocysts (the sac-like structure inside of which actinospores form). Development of actinospores within each pansporocyst was roughly synchronous, but asynchronous between pansporocysts. This meant a range of stages were captured in section, allowing for the interpretation of a developmental sequence for the sporoplasm.

Figure 1. Generalized myxosporean spore development within an oligochaete based on El-Matbouli & Hoffmann (1998). Following a proliferation, binucleate stages transform into pansporocysts, multicellular sac-like stages within which actinospores form. (1) Within the pansporocyst, cell division followed by fusion results in eight ‘zygotes’ (Z). (2) Each zygote divides twice. Three cells surround the remaining cell to form a sporoblast. (3) The sporoblast initially consists of three sporogenic cells (S) surrounding an internal cell (termed generative cell by El-Matbouli & Hoffmann 1998). (3–4) Transitional stages represented by ?, under debate in this paper; the two alternative interpretations are shown in figure 9 pathways A and B i–iii. (4) The sporoblast transforms into three capsulogenic cells (C) and three valvogenic cells (V). A single sporoplasm is attached to the valvogenic cells. The sporoplasm comprises a multinucleated somatic cell within which germ cells reside. Each germ cell is contained within a tightly fitting vacuole. (5) The sporoplasm enters the cavity formed by the differentiated V and C cells and a mature actinospore is formed. When this is released from the host into water, the V cells expand to form three processes that aid floatation. The shape of the processes defines the actinospore type—in this case an aurantiactinomyxon.

Figure 2. Sporoblasts formed when one germ cell (G) is entirely surrounded by at least three sporogenic cells (S). Division of these sporogenic cells presumably occurs during the encirclement of the germ cell. Scale bar, 2.5 μm.

(a) **Sporoblast**
The initial stage of sporoplasm formation, observed within pansporocysts, was the sporoblast. This structure was composed of a centrally positioned germ cell, enclosed by at least three sporogenic cells, the two cell types separated by a conspicuous fluid-filled space (figure 2). The sporogenic cells were connected together by dense adherens junctions, whereas filopodia were noted extending from the internal germ cell(s) suggesting a contact with the surrounding cells. Both the germ and sporogenic cells underwent division (figure 3). In sections where sporoblasts possessed few cells, the sporogenic cells appeared positioned roughly equidistant around the germ cell(s), but as cell numbers increased, the sporogenic cells clustered at one pole and appeared differentiated; some cuboidal, whereas others were distended. The maximum number of cells counted in section composing a sporoblast was seven, two germ cells surrounded by five sporogenic cells (figure 4).
Sporoblasts composed of cuboidal cells surmounting distended cells, which surrounded the germ cells, were interpreted to be the next stage of development (figure 5). The cuboidal cells attached to the distended cells by elongated adherens junctions. Owing to the distinctive nature of the cell types and their apparently differing roles during development, the cuboidal cells are now termed valvocapsulogenic (VC) cells and the distended cells, sporoplasmogenic (SP) cells.

**Formation of sporoplasm**

The simplest sporoplasts observed were two germ cells, contained within a somatic, multinucleated surrounding cell, connected at one pole to three VC cells by adherens junctions (figure 6). The connection to the VC cells was either broad, across all three cells or narrow. For the latter configuration, VC cells formed a rounded structure, attached to the sporoplasm by adherens junctions (figure 7).

The most developed sporoblast noted, prior to the differentiation of the VC cells into valve cells and capsulogenic cells, had three apical VC cells that formed a hollow, rounded structure connected by prominent adherens junctions to the sporoplasm to form an isthmus. The sporoplasm was multinucleated and contained many germ cells within it. The germ cells separated from the surrounding cell by a double plasma membrane (figure 8). Evidence for any of the processes associated with endogenous budding was not observed to explain the initial occurrence of germ cells within the sporoplasm.

**4. DISCUSSION**

While some differences can be noted between the myxosporian species observed in this study compared with those of previous ultrastructural studies (notably two cells contained within the early sporoblast as opposed to just one), sporoplasts containing cells in a fluid-filled space and the maturing sporoplasm connected to VC cells by a cytoplasmic isthmus appear consistent across species (El-Matbouli & Hoffmann 1998; Ozer & Wootten 2001). In previous studies, a generative cell (=SP cell) was considered to be the central cell observed in the early sporoblast. The generative cell produced an internal germ cell by endogenous budding resulting in a sporoplasm. The VC cells then separated and the sporoplasm attached to them (figure 9, pathway A). The endogenous budding stage was not demonstrated, only inferred to
explain the resultant structures (Lom & Dyková 1992b; El-Matbouli & Hoffmann 1998; Ozer & Wootten 2001). In examining the development of the aurantiactinomyxon-type myxosporean, endogenous budding does not account for the presence of two cells within the early sporoblast but only one sporoplasm within the actinospore. Instead, it is clear that the sporoplasm forms when the fluid surrounding the two germ cells is removed, collapsing the surrounding SP cells onto them (figure 9, pathway B). Therefore, the previous inferences are not supported. As there is no evidence for endogenous budding within the annelid host, this leads to the question: does endogenous budding occur within the fish host?

The development of myxosporeans in fish has been examined for over a century. Early studies developed the idea of endogenous budding to explain the apparent appearance of internal cells within multinucleated plasmodia, which was commensurate with knowledge of other parasitic protists at the time (Thélohan 1890; Davis 1916; Noble 1944; Shul’man 1966). However, the studies were constrained by the limits of light microscopy and a lack of knowledge concerning myxozoan life cycles. Only one study has previously questioned the existence of endogenous budding, suggesting that the light microscopical evidence supporting it was weak, but this study did not adequately explain the origin of the internal cells (Desser et al. 1983). The advent of electron microscopy, and its use to examine myxozoans, resulted in studies that supported endogenous budding, explaining secondary cell formation by Ceratomyxa shasta and M. cerebralis (Yamamoto & Sanders 1979; El-Matbouli et al. 1995), and of tertiary cell formation in parasites putatively identified as Sphaerospora renicola (Lom et al. 1983). These studies suggested that the formation of an internal cell occurred through the accumulation of ‘cytoplasmic membranes’ or ER around nuclei. All other studies either have not addressed the issue or presumed that it occurs. In addition, with no alternative hypothesis to explain the origin of internal cells, all review articles, which address myxosporean development, have consistently reiterated the existence of endogenous budding (e.g. El-Matbouli et al. 1992; Garden 1992; Lom & Dyková 1992a, 2006; Molnár 1994; Kent et al. 2001; Canning & Okamura 2004; Feist & Longshaw 2006). A similar situation exists for the order Paramyxida of the protistan phylum Cercozoa, the only other group reported to have cell-within-cell development involving internal membranes, comparable to the Myxozoa (Perkins 1976; Ginsburger-Vogel & Desportes 1979; Desportes 1984). Like the Myxozoa, although often cited, any evidence for such development has rarely been documented (Perkins 1976; Desportes 1984).

Studies examining the entire life cycle of Tetracapsuloides bryosalmonae, a myxozoan of the class Malacosporea, the sister taxon to Myxosporea, found that all internal cells, secondary and tertiary, initially originated by cells engulfing one another (Morris & Adams 2007, 2008). A reinterpretation of the literature by Morris & Adams (2008) contended that the origin of all myxosporean tertiary cells, including those of S. renicola, could be accounted for by engulfment. Therefore, the only myxosporean cell type that results from an endogenous budding would be the secondary cell that occurs within the vertebrate phase of development. As secondary cells have been documented as dividing by mitosis, endogenous budding is not required to explain their proliferation, so proof of its occurrence relies on the origin of the first cell doublet, i.e. a primary cell containing a single secondary cell.

Studies that document the origin of cell doublets are lacking (also noted by Lom & Dyková 1992a). The photomicrograph in Yamamoto & Sanders (1979), reputedly demonstrating endogenous budding within the primary cell of C. shasta, appears to show complete cells already formed. The time course study of El-Matbouli et al. (1995) examining M. cerebralis within the fish host identified the initial presence of cell doublets within an
enclosing cell during very early infection, but similarly to Yamamoto & Sanders (1979), did not evidence how the doublets formed. Therefore, despite the numerous studies conducted on myxosporean development, none corroborate endogenous budding.

The origin of internal cells (either secondary or tertiary) by myxozoans has only been noted when cells surround other cells. I propose that the internal cells of all myxozoans initially derive from variations of this method, with division explaining any subsequent intra-cellular proliferation. This trait of internalizing cells, resulting in cell-within-cell complexes, has parallels with the Cnidaria, i.e. the acquisition of algal symbionts by cnidian cells (Benayahu et al. 1992). Therefore, this unusual developmental process, which initially drew comparisons to protistan schizogony, has analogies to the closest relatives of myxozoans. In comparison, endogenous budding that would require a highly specialized process, unique within the animal kingdom but has little to no data supporting its existence, is dogma.

The author would like to thank Mr Linton Brown for assistance processing samples and Dr Darren Green for providing helpful comments on the paper. This study was funded by the Biological and Biosciences Research Council (grant no. BBC 5050421).
