A major challenge in evolutionary biology is to identify the genes underlying adaptation. The oxygen-transporting haemoglobins directly link external conditions with metabolic needs and therefore represent a unique system for studying environmental effects on molecular evolution. We have discovered two haemoglobin polymorphisms in Atlantic cod populations inhabiting varying temperature and oxygen regimes in the North Atlantic. Three-dimensional modelling of the tetrameric haemoglobin structure demonstrated that the two amino acid replacements Met55β1Val and Lys62β1Ala are located at crucial positions of the αβ1 subunit interface and haem pocket, respectively. The replacements are proposed to affect the oxygen-binding properties by modifying the haemoglobin quaternary structure and electrostatic feature. Intriguingly, the same molecular mechanism for facilitating oxygen binding is found in avian species adapted to high altitudes, illustrating convergent evolution in water- and air-breathing vertebrates to reduction in environmental oxygen availability. Cod populations inhabiting the cold Arctic waters and the low-oxygen Baltic Sea seem well adapted to these conditions by possessing the high oxygen affinity Val55–Ala62 haplotype, while the temperature-insensitive Met55–Lys62 haplotype predominates in the southern populations. The distinct distributions of the functionally different haemoglobin variants indicate that the present biogeography of this ecologically and economically important species might be seriously affected by global warming.

1. INTRODUCTION

Elucidating the molecular mechanisms of adaptation is a central aim in evolutionary biology, yet very few studies have identified the genes underlying adaptive variation in fitness-related traits in natural populations. The haemoglobins represent a unique system for studying adaptive changes because these oxygen-carrying proteins closely connect metabolic activities with external conditions. Hence, the haemoglobins have experienced a major evolutionary pressure and acquired a number of complex features to execute their primary function under extreme variable conditions (Perutz 1983). One remarkable instance of natural selection is the mutated haemoglobin of the Andean goose (Chloephaga melanoptera) and bar-headed goose (Anser indicus) enabling these species to tolerate low oxygen pressure at high elevations in the Andean and Himalayan mountains, respectively (Hiebl et al. 1987; Liang et al. 2001). The genetic basis of high-altitude adaptation in the deer mice (Peromyscus maniculatus) has recently been elucidated by identifying several mutations in the 5α globin gene, which showed different genotypes in the elevation zones examined (Storz et al. 2007).

Temperature change strongly affects the oxygen consumption and haemoglobin–oxygen-binding affinity of poikilothermic organisms, as well as the ambient oxygen availability. This crucial environmental factor therefore sets the limits for life by influencing the maintenance and activity of all poikilothermic animals. Accordingly, the impact of global warming on seawater temperatures has been reported to seriously affect both the distribution and production of marine species (O’Brian et al. 2000; Perry et al. 2005; Brander 2007). Thus, the northward shift of
the North Sea populations of Atlantic cod was reported to be due to climate-related changes (Perry et al. 2005), which, however, seems to contrast with the lack of selective behaviour to avoid high temperatures reported in a more recent study (Neat & Righton 2007). The tolerance of marine fishes to not only high, but also low, temperatures is characterized by a discrepancy between the demand for oxygen and the capacity of oxygen supply to the tissues (Lannig et al. 2003; Sartoris et al. 2003; Pörtner & Knust 2007). This emphasizes the temperature-dependent use of functionally different haemoglobin isoforms to optimize oxygen transport. The nucleated red blood cells of fishes are generally characterized by multiple haemoglobin components, which are functionally different and appear adapted for oxygen extraction in habitats that may vary in oxygen, temperature and carbon dioxide (Pérez et al. 1995; Berenbrink et al. 2007). The heterogeneity of fish haemoglobins is further increased in Atlantic cod through the display of population-specific haemoglobin phenotypes designated HbI-1/1, HbI-2/2 and HbI-1/2 (Sick 1961).

Atlantic cod is believed to comprise several more or less reproductively isolated populations of seasonal migrants and sedentary residents (Robichaud & Rose 2004; Pampoulie et al. 2008; Wennevik et al. 2008), which seem to be differentially adapted to the varying physico-chemical conditions in the Arctic and temperate regions of the North Atlantic (Nelson et al. 1996; Nissling & Westin 1997; Brix et al. 1998). The distribution of the cod haemoglobin phenotypes is extremely heterogeneous in the North Atlantic (Brix et al. 1998; Pörtner et al. 2001): the homozygote HbI-2/2 type predominates in the colder northern waters, whereas the homozygote HbI-1/1 type is prevalent at lower latitudes along the coast of Norway and in the North Sea. A similar, although less clear,cline can be seen along the North American East Coast (Sick 1965a). Accordingly, Petersen & Steffensen (2003) showed that temperature is a selective factor in the distribution of the haemoglobin phenotypes by demonstrating that HbI-2/2 cod prefer lower temperatures (8.2°C) than HbI-1/1 cod (15.4°C) under normoxic conditions. These results fit with oxygen-binding analyses demonstrating that the HbI-2/2 phenotype shows higher oxygen-binding affinity than HbI-1/1 fishes at low temperatures (less than 12°C), while the situation is reversed at higher temperatures up to 20°C (Karpov & Novikov 1980; Brix et al. 1998, 2004). The HbI-1/2 heterozygote seems to display intermediate properties of the two homozygotes.

In this study, we reveal the long-sought genetic basis of the haemoglobin polymorphism in Atlantic cod and present molecular mechanisms underlying the proposed adaptation of the cod populations to varying temperature and oxygen regimes. We first determine the relationship between the conventional haemoglobin phenotypes and sequence polymorphisms in the cod globins. Second, we infer from three-dimensional modelling of the tetrameric haemoglobin structure that the identified amino acid replacements influence the haemoglobin quaternary structure and electrostatic features, and thereby its oxygen-binding properties. Finally, we show that the allelic distribution of the haemoglobin polymorphisms in Atlantic cod populations is related to environmental temperature and oxygen saturation.

2. MATERIAL AND METHODS

(a) Cloning of cod globin genes

Templates for polymerase chain reaction (PCR) amplification of α and β globin genes were isolated from the spleen and blood of juvenile Atlantic cod caught in the sea off Bergen and Trondheim, Norway, and in Øresund, Denmark. The tissues were stored in RNAlater (Ambion, Foster City, CA, USA) until extraction of total RNA (Trizol, Gibco BRL, Gaithersburg, MD, USA) and cDNA synthesis (Pharmacia Biotech, Piscataway, NJ, USA). Design of PCR primers was based on gadoïn globin sequences available in public databases, and primer sequences are available upon request. PCR was performed under standard protocols, the amplicons were inserted in pGE-M-T Easy Vector (Promega, Fitchburg, WI, USA) and globin-encoding sequences were obtained by sequencing multiple clones in both directions with BigDye v. 3.1 sequencing kit on 3730 ABI DNA analyser (Applied Biosystems, Foster City, CA, USA).

Haemoglobin genotype–phenotype relationships were determined by studying globin sequence variation in a group of 35 juvenile fish caught in the sea off Bergen, which were phenotyped by isoelectric focusing (IEF) analysis of haemolysates (Fyhø et al. 1994). The fish were genotyped using erythrocyte cDNA and genomic DNA as templates for the PCR amplification and direct sequencing (Applied Biosystems) of polymorphic sites identified in the Hb-β1, Hb-β2, and Hb-α2 genes (figure 1).

(b) Globin genotyping

A total of 363 Atlantic cod were sampled from different localities representing the stocks of northeast Arctic cod, Norwegian and Danish coastal cod, and Baltic cod. Genomic DNA was extracted from gill arches or muscle tissue, and genotyping was performed by single nucleotide polymorphism (SNP) analysis. PCR primers were designed using the software SPECTRODESIGNER v. 3.0 (Sequenom) and hybridized to invariable sequences of the Hb-β1 gene. The 5′ and 3′ capture primers flanked the polymorphic positions of Met55Val and Lys62Ala, and the sequences are 5′-ACTGTGTTGATGATTCGTCCATGTGGTCCAG-3′ and 3′-ACTGTGGATGCTACTTTGCTAGTTGGCCG-3′, respectively. The mutation A/G in the first position of the Met (ATG) or Val (GTG) codon was determined by studying globin sequence variation in a group of 35 juvenile fish caught in the sea off Bergen, which were phenotyped by isoelectric focusing (IEF) analysis of haemolysates (Fyhø et al. 1994). The fish were genotyped using erythrocyte cDNA and genomic DNA as templates for the PCR amplification and direct sequencing (Applied Biosystems) of polymorphic sites identified in the Hb-β1, Hb-β2, and Hb-α2 genes (figure 1).

(c) Model building

The predicted sequences of the cod globin chains were submitted to the NCBI–Blast server and aligned with homologous sequences using CLUSTALW. The α- and β-globins of Antarctic rock cod Trematomus bernacchii (Protein Data Bank (PDB) code 1HH1), the Dusky notothen Trematomus nevoni (PDB code 2AA1), bluefin tuna Thunnus thynnus (PDB code 1V4W), and rainbow trout Oncorhyncus mykiss (PDB code 1OUT), shared the
highest sequence identity with the cod globins and were selected as templates for homology modelling. Each chain model was built by comparative modelling using the MODELLER program v. 7 (Sali & Blundell 1993) as implemented in INSIGHTII (Accelrys Inc., San Diego, CA, USA) and using the crystallographic structures of the four fish haemoglobins. Three structural models were created for each globin chain in Atlantic cod, and the best model was selected based on the MODELLER objective function ($F$, molecular probability density function violation) and the stereochemical criteria of PROCHECK (Laskowski et al. 1996).

The monomeric $\alpha$ and $\beta$ chains obtained by homology modelling were superimposed onto the crystal structure of the $T. bernacchii$ haemoglobin to keep the same relative orientation of the four subunits. The majority of the residues of the model structures were found to occupy the most favoured regions of Ramachandran plots, and the other residues occupied the additional allowed regions. Structural manipulations and energy minimization of the four tetrameric combinations of Met55$\beta$Val and Lys62$\beta$Ala were performed using the molecular modelling program InsightII (Accelrys) and the CHARMM force field (Brooks et al. 1983).

**GRID analysis**

The hydrophobic and polar characteristics of the distal environment of the haem pocket were investigated with the GRID program. The interaction of a probe group with a protein of known structure is computed at sampled positions throughout and around the macromolecule, giving an array of energy values. GRID was used to predict the most favourable position for a water molecule near the distal His63$\beta$ of the alternative pockets attributable to the Lys62$\beta$Ala polymorphism. The probe used in the calculations was the water group (OH2), and the grid spacing was set to 0.25 Å. Using the flexibility option of the program, the flexible side chains of the protein can move in response to the probe and therefore mimic the adjustments that occur upon ligand binding. The results are displayed by INSIGHTII (Accelrys) as contour maps showing regions of the $\beta$ haem pocket, which favourably interact with the hydrophilic probe.

**Statistical analyses**

Departure from Hardy–Weinberg proportions within cod samples was estimated as $F_{IS}$, and population differentiation, $F_{ST}$, between sample pairs was evaluated using the estimator $\theta$ (Weir & Cockerham 1984). Calculations and statistical

testing of $F_{\text{IS}}$, $F_{\text{ST}}$ and genotypic disequilibrium between loci were performed using GENEPop on the web (Raymond & Rousset 1995).

3. RESULTS

(a) Genotype–phenotype relationships

We searched for polymorphic genes responsible for the conventional haemoglobin phenotypes in Atlantic cod by isolating six genetically distinct globins from reverse-transcribed erythrocyte mRNA using PCR. The identified globins comprise two $\alpha$ chains (Hb-$\alpha_1$ and Hb-$\alpha_2$) and four $\beta$ chains (Hb-$\beta_1$, Hb-$\beta_2$, Hb-$\beta_3$, and Hb-$\beta_4$), and consist of 143 and 147 amino acids, respectively (figure 1a). Amino acid polymorphisms were identified in three of these globins by studying variation in the coding sequences. The Hb-$\beta_1$ gene contains three non-synonymous mutations resulting in the replacement of Val55 with Met55 and Lys62 with Ala in Atlantic cod haemoglobin phenotypes, in contrast to the polymorphic Hb-$\alpha$2 gene, the expressed cDNA and the tetramer 2 and 3 of Atlantic cod comprise three different tetrameric properties of the cod haemoglobins. As the haemoglobins in Atlantic cod comprise three different tetrameric structures designated Hb1, Hb2 and Hb3 (Verde et al. 2006), the quaternary structure of the $\beta_1$-containing Hb1 tetramer $x_1x_1\beta_1\beta_1$ was built by three-dimensional homology modelling using the crystallographic structures of the $\alpha$- and $\beta$-globins of four teleost species as templates. In the tetrameric cod haemoglobin, the position of Met55Val is close to Pro120 and the Hb-$\alpha_1$ subunit interface (figure 2). The calculated distances of the CG atom of Met55Val and Lys62Ala and to the CG2 atom of Val55 and Lys62 were identified as the key residues contributing to the hydrophilic contour maps.

(b) Structure–function relationships

We then addressed the functional impact of the Met55Val and Lys62Ala replacements on the oxygen-binding affinity (Springer et al. 1994). We estimated the binding energy of a water probe with the distal haem pocket of the Lys62 and Ala62 variants to $-14.8$ and $-11.6$ kcal mol$^{-1}$, respectively, demonstrating the stronger water interaction with the polar Lys compared with the Ala residue. Differences in the water interaction patterns in the two alternative pockets are evident in the calculated GRID contour maps (figure 3). The interaction area is significantly larger in the Lys62-containing pocket due to
Table 1. Cod homozygous for the Val–Ala haplotype and Lys haplotypes prevailed in the populations examined possibly due to population mixing. The Val–Ala and Met–Ala material). This sample showed a deficit of heterozygotes, conformed to Hardy–Weinberg expectations, except at warmer areas of the North Sea (Frydenberg 90%) and Baltic Sea (96%), decreasing to 28–36% in the warmer areas of Greenland (99%), Iceland (98%), northern Norway (90%) and Baltic Sea (96%), decreasing to 28–36% in the warmer areas of the North Sea (Frydenberg et al. 1965; Sick 1965a,b). Allele frequencies within samples generally conformed to Hardy–Weinberg expectations, except at Malangen (table 2 in the electronic supplementary material). This sample showed a deficit of heterozygotes, possibly due to population mixing. The Val–Ala and Met–Lys haplotypes prevailed in the populations examined (table 1). Cod homozygous for the Val–Ala haplotype (corresponding to the HbI-2/2 phenotype) comprised 80–94% of the individuals in populations of the Baltic Sea and the northern waters, whereas homozygotic Met–Lys cod (HbI-1/1 phenotype) were completely lacking in these populations. Met–Lys homozygotes were mainly found in the mid- and southern populations together with the double heterozygotes. There was a significant linkage disequilibrium between the two loci (table 3 in the electronic supplementary material), but it is unclear to what extent heterozygotes are coupled (Met–Lys/Val–Ala) or repulsive (Met–Ala/Val–Lys). Intragenic recombination events have apparently occurred as indicated by the additional genotypes sparsely distributed in the populations examined (table 1). Consistently, sporadic subtypes of the cod haemoglobins have been reported along the Norwegian coast and in Danish waters, differing from the main types in IEF-banding patterns, oxygen-binding affinities and body growth rates (Fyhn et al. 1994; Brix et al. 2004; Husebø et al. 2004; Imsland et al. 2007).

4. DISCUSSION

(a) Globin polymorphism and oxygen binding

This study presents strong evidence for the crucial role played by the polymorphic β1-globin in the adaptation of Atlantic cod to varying temperature and oxygen regimes. The unambiguous association between haemoglobin phenotypes and genotypes determined in both genomic DNA and expressed cDNA strongly supports Hb-β1 as the active gene responsible for the protein alleles HbI-1 and HbI-2. This is further strengthened by the different isoelectric point of the Met55–Lys62Val (pI 7.68) and the Val55–Ala62 (pI 6.99) variants, which is in agreement with the HbI-1–specific cathodic band as visualized by the IEF analysis (Sick 1961; Fyhn et al. 1994). Furthermore, the Met55Val replacement explains the appearance of an HbI-1–specific cathodic fragment in the fingerprinting analysis of chymotrypsin-digested cod haemoglobin (Rattazzi & Pik 1965). This His-containing peptide matches perfectly the acidic (pI 10.81) peptide 56GNYPKVAKH62 resulting from low-specific chymotrypsin cleavage at Met55, whereas treatment of the Val55 variant leaves the neutral (pI 7.55) peptide 49STDAAVLVGVPKVAH62 uncleaved. The latter peptide was apparently not recognized by Rattazzi & Pik (1965).

The Met55Val and Lys62Ala replacements occur at the key positions of the β1 subunit interface and haem pocket, respectively, and are therefore proposed to affect the oxygen-binding properties of cod haemoglobin. The β1 contact is crucial to the stability of the dimers, and any gap loosening this 1 interaction destabilizes the low-oxygen affinity deoxy state and facilitates transition to the high-affinity oxy state (Abbas & Luftullah 2002; Shikama & Matsuoka 2003). Consistently, increased oxygen affinity was induced in human haemoglobin by site-directed mutagenesis of Met55→Ser or Pro119→Ala (corresponding to cod Pro120z), which both excluded van der Waals contact at this subunit interface (Jessen et al. 1991). It is noteworthy that either of these crucial positions is mutated in the haemoglobin of the hypoxia-tolerant Andean goose (Leu55→Ser) and bar-headed goose (Pro119z→Ala), when compared with the greylag goose (Anser anser) living in the plains and displaying normal oxygen affinity (Hiebl et al. 1987; Liang et al. 2001). In Atlantic cod, changing Met55 with the smaller Val residue increases the gap between the β1 subunits that probably destabilizes the T-structure with a resultant
increase in oxygen-binding affinity, as demonstrated in the human Met55β→Ser mutant (Jessen et al. 1991). We therefore propose that, during the process of convergent evolution, the water-breathing cod and air-breathing goose have acquired the same molecular mechanism for high-efficiency oxygen binding. The exploitation of the same position for tolerating hypoxic conditions in such diverse species strongly supports the hypothesis of Perutz (1983) that adaptive changes in haemoglobins have evolved by only a few amino acid substitutions in key positions.

The second polymorphism Lys62βAla in the cod β1 globin is located close to the highly conserved His63β on the distal side of the haem. The distal His plays a key role in oxygen binding by regulating ligand access to the haem pocket and by affecting the energetics of the oxygen fixation (Olson et al. 1988; Maréchal et al. 2006). In Atlantic cod, the replacement of Ala62β with the polar Lys residue does not introduce any significant steric effects on K for the amino group than the aliphatic group, with the transfer of an amino group or an aliphatic group from a non-polar solvent to water is energetically more favourable (Ooi & Oobataka 1988). Apparently, this is essentially due to the more exothermic water interaction of the former as compared with the latter group, showing a D∆H of −192 and −26 cal mol$^{-1}$ Å$^{-2}$, respectively (Ooi & Oobataka 1988). Consequently, at lower temperatures the oxygen path to the haem iron is restricted, being hindered by the stronger water interaction with Lys62β than with the Ala62β residue. The emerging mechanistic picture is consistent with the observation that the oxygen affinity of the HBα-1/1 (Met-Lys) form is much less temperature-sensitive than that of the HBα-2/2 (Val-Ala) form (Brix et al. 2004), due to the counterbalance between two exothermic reactions: the internal water interaction and oxygen binding to haem.

(b) Cod in the Baltic Sea

The strong shift in allele frequencies at the entrance to the Baltic coincides with the differentiation in cod at selectively neutral microsatellite DNA markers (Nielsen et al. 2003). However, the degree of differentiation found in the Hb-β1 locus between the Kattegat and Baltic cod (F$ST$=0.480, 0.472; table 1 in the electronic supplementary material) is more than one order of magnitude higher than that shown for neutral genetic markers (F$ST$=0.034), and is thus consistent with the divergent selection between different environments. It might be speculated that the complete dominance of cod with the Val-Ala variant in the Baltic Sea could be the result of the colonization by Barents Sea cod at 8000–4000 yr ago, as hypothesized by Sick (1965b). This is, however, not supported by microsatellite studies demonstrating a closer relationship between the Baltic and North Sea cod than that between the Baltic cod and cod from the Barents Sea (Nielsen et al. 2001).

The brackish water of the Baltic Sea restricts cod to deeper waters with higher salinity, but this strategy is compromised by low oxygen levels near the sea bottom due to water stagnation (Tomkiewicz et al. 1998). The Baltic cod are also challenged by long periods of low temperatures during winter and spring, which might, however, be an advantage by lowering the metabolic rate and increasing the oxygen solubility. In addition to the reported local adaptation of the Baltic cod eggs and sperm to low salinity (Nisling & Westin 1997), we propose that the Baltic cod stock is adapted to environmental hypoxia by possessing the high-affinity Val-Ala (HbI-2/2) form. Owing to the temperature sensitivity of this haemoglobin variant, its oxygen affinity would further increase with decreasing temperatures because of the strong exothermic character of oxygen binding.

(c) Cod in the Arctic waters

In the cold waters of the Northern Hemisphere, fishes are well known to possess high mitochondrial densities and elevated aerobic capacities, which are crucial traits in thermal adaptation (Guderley 2004; Pörtner et al. 2006). Accordingly, permanent cold adaptation in Atlantic cod inhabiting the Barents Sea and the Norwegian coast involves elevated aerobic metabolism in white muscle compared with the North Sea cod, in line with the concept of higher maintenance costs at low temperatures (Lannig et al. 2003). Increased oxygen delivery to high mitochondria densities is also supported by the
significantly higher cardiac expression of myoglobin in fish acclimatized to 4°C than 10°C, and the cold compensation was more pronounced in the northeast Arctic cod than North Sea cod (Lurman et al. 2007). Hbl-2/2 cod acclimatized to 4°C showed significantly higher oxygen affinities than Hbl-1/1 cod (P50 of 45.64 and 53.77 mmHg, respectively, and Pao2 of 130.79 and 177.28 mmHg, respectively), and larger arterial–venous differences were found in Hbl-2/2 cod compared with the Hbl-1/1 type when measured at 4°C (Brix et al. 2004). The importance of oxygen loading by high-affinity haemoglobins in water-breathing animals is supported by comparative studies of multiple water-breathing, bimodal and air-breathing fish species (Graham 2006).

Thus, safeguarding post-branchial saturation seems to be given the first priority in a low-oxygen medium. Even though information about the ligands affecting both the arterial and venous site is limited in cod, the presented results strongly indicate that the high-affinity Val–Ala form is well adapted to the cold Arctic waters by ensuring high oxygen saturation of the arterial blood that is of importance for the high maintenance costs. The related ice cod (Arctogadus glacialis) and polar cod (Boreogadus saida) are strictly cold-water species, but the relatively stationary ice cod inhabits permanently ice-covered waters even farther north than the highly migratory polar cod. Physiological studies of a purified haemoglobin component (Hb3) revealed lower oxygen affinity, but higher Bohr effect, in the ice cod compared with both polar cod and Atlantic cod, which may be preferentially related to lifestyle (Verde et al. 2006). Intriguingly, the β globin of ice cod and polar cod differs by displaying Met and Val, respectively, at position 55 (similar residues Gln and Asn at position 62; SwissProt accession nos. Q1AGS3, Q1AGS7). Based on the results herein, we suggest that the low-affinity Met variant probably transport sufficient amounts of oxygen in the sluggish ice cod, whereas the polar cod is probably better fitted to higher oxygen demands by possessing the destabilizing Val residue at the z4β1 interface, similar to the Atlantic cod in these waters.

Cod in the North Sea

Studying the effects of acclimation temperatures at 4 and 12°C, Brix et al. (2004) found a significant drop in oxygen affinity in Hbl-2/2 cod compared with Hbl-1/1 cod when acclimatized to and measured at 12°C. Cod possessing the temperature-sensitive Val–Ala form will therefore risk reduced oxygen uptake at higher temperatures. Accordingly, both oxygen-binding affinity and capacity decreased with acute temperature increases in cod from Newfoundland, which probably comprised much more than 90 per cent Hbl-2/2 (Gollock et al. 2006). The large, exponential increase in blood flow measured in these Newfoundland cod differs from the hyperbolic increase in German Bight cod likely to be composed of more than 55 per cent Hbl-1/1 (Lannig et al. 2004). Although different techniques may account for some of the observed differences between these studies, the unexpected resistance to warming waters specifically reported for the North Sea cod (Neat & Righston 2007) is highly suggestive of the possible great importance of the temperature insensitivity of the Hbl-1/1 form. We therefore propose that cod possessing the Met–Lys form is better fitted for life in warmer waters than cod with the Val–Ala form, in agreement with the preference for higher temperatures by the Hbl-1/1 cod than the Hbl-2/2 fish (Petersen & Steffensen 2003).

Interestingly, acclimation of heterozygotes Hbl-1/2 to high temperature was shown to involve increased levels of the Hbl-1 protein allele in the blood, whereas low temperature favoured the synthesis of the Hbl-2 allele (Brix et al. 2004). Hence, the ability to change the ratio of the two haemoglobin forms by a hitherto unknown mechanism might be beneficial for the heterozygotic cod in these fluctuating environments.

Concluding remarks

The distributions of both the exploited and unexploited North Sea fish populations have responded markedly to recent increases in sea temperatures as a consequence of global warming (O’Brian et al. 2000; Perry et al. 2005). Based on the strong relationship between the haemoglobin polymorphisms and temperature preference, we propose that the observed northward migration of Atlantic cod is due to increased temperatures exceeding that preferred by the Hbl-1/1 (Met–Lys) cod in the North Sea. This implies further that a combination of increased water temperature (HELCOM 2007) and low oxygen levels would be even more unfavourable for the Baltic Sea cod, which predominantly possess the Hbl-2 allele. The present frequency of the Hbl-2 allele in the Baltic (approx. 97%) is, however, similar or even higher than that identified by Sick in the early 1960s (Sick 1965b), indicating either lack of environmental change or microevolutionary response during this time period.

We thank S. W. Omholt and R. Wilson for their discussions and reading of the manuscript. S. E. Fevolden is gratefully acknowledged for providing us with cod samples. This work was supported by the Norwegian Research Council and the Swedish Research Council FORMAS. The work was carried out under National Animal Board licences.
